Analysis of Gene Diversity in Subdivided Populations

(population structure/ genetic variability/heterozygosity/gene differentiation)

Communicated by Sewall Wright, August 6, 1973

ABSTRACT A method is presented by which the gene diversity (heterozygosity) of a subdivided population can be analyzed into its components, i.e., the gene diversities within and between subpopulations. This method is applicable to any population without regard to the number of alleles per locus, the pattern of evolutionary forces such as mutation, selection, and migration, and the reproductive method of the organism used. Measures of the absolute and relative magnitudes of gene differentiation among subpopulations are also proposed.

In a genetic study of substructured populations, Wright (1-3) showed that the variation in gene frequency among subpopulations may be analyzed by the fixation indices or F-statistics. He derived the formula

$$1 - F_{IT} = (1 - F_{IS})(1 - F_{ST}),$$

where $F_{IT}$ and $F_{IS}$ are the correlations between two uniting gametes to produce the individuals relative to the total population and relative to the subpopulations, respectively, while $F_{ST}$ is the correlation between two gametes drawn at random from each subpopulation. $F_{IT}$ and $F_{IS}$ may become negative, but $F_{ST}$ is non-negative. The degree of gene differentiation among subpopulations may be measured by $F_{ST}$.

The F-statistics are applicable to any population if there are only two alleles at a locus. In the presence of multiple alleles, however, Eq. 1 no longer holds except for the special case of random differentiation with no selection (4). Recently, I (5, 6) proposed a new method of measuring the degree of gene differentiation between a pair of populations. This method is based on the identities of two randomly chosen genes within and between populations and independent of the number of alleles. In the following, I shall extend this method to the case of hierarchical structure of populations and show that the gene-frequency variation in a substructured population can be analyzed directly in terms of heterozygosity or of gene diversity, which will be defined later. This method can be applied to any population without regard to the number of alleles at a locus or to the pattern of evolutionary forces such as mutation, selection, and migration. It is also applicable to any organism, whether this is sexually or asexually reproducing or whether this is diploid or nondiploid, as far as gene frequencies can be determined. Such a method seems to be necessary to analyze rapidly increasing data on gene frequencies for protein loci.

Suppose that there are $n$ alleles at a locus and the frequency of the $k$th allele is $x_k$ in a population. The probabilities of identity and nonidentity of two randomly chosen genes are then given by $J = x_k^2 k$ and $H = 1 - J$, respectively. The probability of nonidentity, $H$, is a measure of genetic variation of a population and usually called heterozygosity. This word, however, is not appropriate for a nonrandom mating population. Therefore, I use the word gene diversity for this quantity. I also use the abbreviated word gene identity for $J$. Of course, if one is interested only in random mating populations, the words gene diversity and gene identity in the following may be replaced by heterozygosity and homozygosity, respectively.

Let us now consider a population that is subdivided into $s$ subpopulations. Let $x_{ik}$ be the frequency of the $k$th allele in the $i$th subpopulation. The gene identity in this subpopulation is given by

$$J_i = \sum_k x_{ik}^2,$$

while the gene identity in the total population is

$$J_T = \sum_k x_k^2,$$

where $x_k = \sum_i w_i x_{ik}$, in which $w_i$ is the weight for the $i$th subpopulation ($\sum_i w_i = 1$). The quantity $J_T$ may be written as

$$J_T = \sum_k (\sum_i x_{ik})^2$$

$$= \sum_k (\sum_i w_i x_{ik}^2) + \sum_i w_i \sum_k x_{ik} x_{ij}.$$  

If $w_i = 1/s$, then

$$J_T = (\sum_k x_{ik}^2 + \sum_{i<j} x_{ik} x_{ij})/s^2$$

$$= (\sum_i J_i + \sum_{i<j} J_{ij})/s^2,$$

where

$$J_{ij} = \sum_k x_{ik} x_{jk}$$
is the gene identity between the \( r \)th and \( j \)th subpopulations.

Let us now define the gene diversity between the \( r \)th and \( j \)th populations as

\[
D_{rj} = H_{rj} - (H_r + H_j)/2
= (J_r + J_j)/2 - J_{rj},
\]

where \( H_r = 1 - J_r \) and \( H_{rj} = 1 - J_{rj} \). I (6, 7) have called this parameter the minimum number of net codon differences per locus, but in the present context the word gene diversity seems to be better. Note that \( D_{rj} \) is \( \sum (x_{r} - x_{j})^2/2 \), so that it is nonnegative. If we use Eq. 6, Eq. 4 reduces to

\[
J_T = \left[ \sum_i J_i + \sum_{i \neq j} (J_j + J_i)/2 - \sum_{i \neq j} D_{ij} \right]/s^2
= \left[ s \sum_i J_i - \sum_{i \neq j} D_{ij} \right]/s^2,
\]

since \( D_{st} = 0 \). Therefore,

\[
J_T = (\sum_i J_i)/s - (\sum_{i \neq j} D_{ij})/s^2
= J_S - D_{ST},
\]

where \( J_S \) is the average gene identity within subpopulations, and \( D_{ST} \) is the average gene diversity between subpopulations, including the comparisons of subpopulations with themselves. The gene diversity in the total population \( (H_T = 1 - J_T) \) is

\[
H_T = H_S + D_{ST},
\]

where \( H_S = 1 - J_S \). Thus, the gene diversity in the total population can be analyzed into the gene diversities within and between subpopulations.

The absolute magnitude of gene differentiation among subpopulations may be measured by \( D_{ST} \) or \( D_m \) given later, while the gene differentiation relative to the total population is given by

\[
G_{ST} = D_{ST}/H_T.
\]

The latter measure depends on the population used, and the estimate obtained in one population cannot be compared with that of another, unless the breeding system is similar for the two populations. If \( H_S \) is small, \( G_{ST} \) may be very large even if the absolute gene differentiation is small. \( G_{ST} \) is equivalent to Wright’s \( F_{ST} \), and we call it the coefficient of gene differentiation. If there are only two alleles at a locus, it can be shown that \( H_T = 2\bar{x}(1 - \bar{x}) \) and \( D_{ST} = 2\sigma_x^2 \), where \( \bar{x} \) and \( \sigma_x^2 \) are the mean and variance of the frequency of an allele among subpopulations, respectively. Therefore, \( G_{ST} \) becomes identical to \( F_{ST} \), which is defined as \( \sigma_x^2/\{\bar{x}(1 - \bar{x})\} \). This property was noted by H. Harpending (personal communication) in a numerical computation.

S. Wright (personal communication) also pointed out that in the case of multiple alleles, \( G_{ST} \) is equal to the weighted average of \( F_{ST} \) for all alleles, i.e.,

\[
F_{ST} = \sum_k \sigma_x^2 \cdot \frac{(1 - \bar{x}_k)}{\sum_k \bar{x}_k},
\]

where \( k \) refers to the \( k \)th allele.

From Eqs. 8 and 9 we obtain the equation \((1 - G_{ST}) \) \( (1 - J_T) = 1 - J_S \). The difference between this equation and Eq. 1 occurs because \( F_{ST} \) and \( F_{ST} \) in Eq. 1 measure the deviations of genotype frequencies from Hardy–Weinberg proportions, while \( J_S \) and \( J_T \) are gene identities. Note that \( G_{ST}, J_T, \) and \( J_S \) are all nonnegative.

As mentioned earlier, \( D_{ST} \) includes the comparisons of subpopulations with themselves. If we exclude these comparisons, we have the interpopulational gene diversity defined as

\[
D_m = \sum_{i \neq j} D_{ij}/s(s - 1)
= sD_{ST}/(s - 1).
\]

This absolute measure of gene differentiation is independent of the gene diversity within subpopulations, and thus it can be used for comparing the degrees of gene differentiation in different organisms. \( D_m \) may also be used to compute the interpopulational gene diversity relative to the intrapopulational gene diversity \( (7) \). That is,

\[
R_{ST} = D_m/H_S.
\]

Formula 8 can easily be extended to the case where each subpopulation is further subdivided into a number of colonies. In this case, \( H_S \) may be analyzed into the gene diversities within and between colonies \( (H_C \) and \( D_{CS} \) respectively). Therefore,

\[
H_T = H_C + D_{CS} + D_{ST}.
\]

This sort of analysis can be continued to any degree of hierarchical subdivision. The relative degree of gene differentiation attributable to colonies within subpopulations can be measured by \( G_{CS(CT)} = D_{CS}/H_T \). It can also be shown that \((1 - G_{CS}) \) \( (1 - G_{ST})H_T = H_C \), where \( G_{CS} = D_{CS}/H_S \). Expression 12 was derived on the basis of two levels of hierarchies. If we disregard the level of subpopulations, we have \( H_T = H_C + D_{CT} \), where \( D_{CT} \) is the gene diversity between colonies within the total population. Therefore,

\[
D_{CT} = D_{CS} + D_{ST}.
\]

In his study of human diversity, Lewontin (8) made an analysis of gene-frequency variation analogous to Eq. 12, by using the Shannon information measure. However, this measure is not directly related to any genetic entity, and it is difficult to make a genetic interpretation of the components corresponding to those in Eq. 12.

Let us now consider the components of the gene diversity \( D_{ST} \) between two subpopulations that are composed of \( r \) and \( s \) colonies. Let \( x_{r k} \) and \( y_{sk} \) be the frequencies of the \( k \)th allele in the \( r \)th colony of the first subpopulation and the \( j \)th colony of the second, respectively. By definition,

\[
D_{ST} = (J_{r} + J_{j})/2 - J_{rj},
\]

where subscripts 1 and 2 refer to the first and second
populations, respectively. From Eq. 7, \( J_{st} = J_{ct} - D_{ct} \) (\( i = 1, 2 \)). On the other hand,

\[
J_{st} = \sum_{k} x_k y_{-k}
\]

\[
= \sum_{i} \sum_{j} \sum_{k} x_{ik} y_{jk} / (rs).
\]

Let \( D_{ij} = (J_i + J_j)/2 - J_{ij} \), where \( J_i = \sum_{k} x_{ik}^2 \), \( J_j = \sum_{k} y_{jk}^2 \), and \( J_{ij} = \sum_{k} x_{ik} y_{jk} \). Then,

\[
J_{st} = \sum_{i} \sum_{j} [(J_i + J_j)/2 - D_{ij}] / (rs)
\]

\[
= (J_{ct} + J_{ct})/2 - D_{ct},
\]

where \( D_{ct} = \sum_{i} D_{ij} / (rs) \). Therefore, we have

\[
D_{st} = D_{ct} - (D_{ct} + D_{ct})/2. \tag{14}
\]

Namely, the gene diversity between two subpopulations is equal to the average gene diversity between a pair of colonies, one from each of the two subpopulations, minus the average gene diversity between the colonies within subpopulations. Formula 14 may be used for estimating \( D_{ct} \) from \( D_{st} \) and \( (D_{ct} + D_{ct})/2 \). It is noted that if we take the average of \( D_{st} \) over all combinations of subpopulations, it reduces to \( D_{st} \) in Eq. 13, as expected.

So far we have considered only a single locus, but the present method is applicable to any number of loci, if we replace the gene diversity for a locus by the average gene diversity for all loci studied. In fact, in order to know a general picture of gene differentiation among subpopulations, a large number of loci that is a random sample of the genome should be used, including both polymorphic and monomorphic loci (7).

In the present paper, we were mainly concerned with the gene differentiation among closely related geographical populations. If the degree of gene differentiation is large, as is the case with a group of subspecies, and \( J_{ss} \) is much smaller than \( J_{st} D_{ss} \) in Eq. 7 (or \( D_{ss} \) in Eq. 10) is not a good measure of differentiation. In this case a better estimate may be obtained by \( D_{st} = -\log_e(J_{ss}/J_{st}) \), in analogy with the genetic distance discussed in my earlier paper (9). Similarly, a better estimate of \( G_{ss} \) may be obtained by \(-\log_e(J_{ss}/J_{st}) / [1 - \log_e J_{ss}] \).

I thank Dr. Sewall Wright for his valuable comments on the manuscript of this paper. This work was supported by U.S. Public Health Service Grant GM 20993.
